**Correspondence:** Brett Morgan ([brettmorgan2@gmail.com](mailto:brettmorgan2@gmail.com))

**Abstract.** The recent proliferation of high quality global gridded GIS datasets has spurred a renaissance of studies in many fields, particularly biogeography. However these data, often 1 km at the finest scale available, are too coarse for applications such as precise designation of conservation priority areas and species distribution modeling, or purposes outside of biology such as city planning and precision agriculture. Further, these global datasets likely underestimate local climate variation because they do not incorporate locally relevant variables. Here we describe a comprehensive set of 30 m resolution rasters for Hong Kong, a small subtropical territory with highly variable terrain where intense anthropogenic disturbance meets a robust protected area system. The data include topographic variables, NDVI, and interpolated climate variables based on weather station observations. We present validation statistics that convey each climate variable's reliability, and compare our results to a widely used global dataset, finding that our models consistently reflect greater climatic variation. To our knowledge, this is the first set of published environmental rasters specific to Hong Kong. We hope this diverse suite of geographic data will facilitate future environmental and ecological studies in this region of the world, where a spatial understanding of rapid urbanization, introduced species pressure, and conservation efforts is critical. The dataset is accessible at <https://figshare.com/s/3a5634e36e80dc33444c>.

## 1 Introduction

Scale of analysis has long been considered a key concern in biogeographic research (Levin, 1992). Multiple types of scale are relevant to environmental data, including analysis grain, response grain, spatial structure, and study extent (Mertes and Jetz, 2018). Analysis grain, the minimum unit of spatial resolution in a spatial grid, is commonly referred to as a pixel or cell. In research that uses environmental raster data, the pixel size directly dictates the types of biogeographic questions that can be reasonably addressed.

This relationship between analysis grain and study suitability is complex, and higher resolutions are not always advantageous. For example, in global analyses excessively high resolution data would be computationally cumbersome and unnecessary if the goal is to characterize broad patterns. However as shown below, many studies have found notable benefits of higher resolution climatic predictors. Unfortunately, regional analyses lacking local data are limited to using global datasets and the grain size at which they are available (e.g. Cheng and Bonebrake, 2017).

Species distribution modeling (SDM) is a common application of gridded environmental data, where the selected analysis grain has important consequences. In SDM, one or more geographic predictors are associated statistically with the location of known observations of a species. The resulting statistical model can be converted to a geographic model: a spatially continuous measure of species occurrence likelihood across the landscape of interest. SDMs are used for many applications, including predicting potential ranges of invasive species, characterizing ecological constraints on species ranges, discovering biodiversity, and planning protected areas (Peterson et al., 2011). The manipulation of SDM grain size is an active area of research. Below, findings on four main effects are summarized: estimated distribution size, inclusion of fine scale features, predictor variable selection, and model predictive ability.

Coarser environmental data consistently result in SDMs that predict larger areas of species presence (Connor et al., 2017; Franklin et al., 2013; Seo et al., 2009). Overestimation of SDMs is especially a concern for conservation purposes, where inferred size of suitable habitat is often used to inform extinction risk assessments. Mistakenly large calculated distributions could result in species that are assigned artificially low risk levels.

Coarse resolution predictors can cause SDMs to omit small, but important areas. Particularly of interest are microrefugia, climatically unique patches of land that can harbor rare species, and are especially important for conservation as species distributions respond to climate change (Dobrowski, 2010). Meineri and Hylander (2016) demonstrated that because high resolution climate models included such microrefugia, the resulting species distribution models predicted lower extinction rates for plant species than coarser predictors. Nezer et al. (2016) found that 10 m or 100 m resolution SDMs can reveal other distribution features invisible at lower resolutions (1 km): movement corridors, isolated habitat patches, geomorphologic features, and anthropogenic effects on distributions.

SDM scale can also affect which predictors are selected for model calculation. Certain predictors may be excluded in SDMs because they lack explanatory power at the chosen scale of analysis (Mertes and Jetz, 2017). For example, vegetation indices like NDVI in fragmented forests are unlikely to be relevant if the grain size is much larger than the forest patch size, because each grid cell will be a single averaged value. This means that coarse models might not only mischaracterize the distribution pattern itself, but they also may fail to explicate important environmental relationships that determine species occurrence. Indeed, Nezer et al. (2016) found that the most important predictors (vegetation, slope) in their highest resolution models (10 m) were "nearly meaningless" at 1 km resolution. Another study found similar differences in predictor importance related to variation in scale (Lasseur et al., 2006). Of course, predictor importance is always relative and thus is subject to which predictors are included in model building. Therefore this pattern is not expected to be observed in all studies, but should not be overlooked as a potential source of bias.

Last, any consistent effects of SDM grain size on the overall predictive ability of SDMs are unclear. The most commonly used measure of SDM performance is Area Under Curve (AUC), where a higher value indicates a greater ability to differentiate between area the species is present or absent. Some studies found increased SDM resolution resulted in increased AUC (Seo et al., 2009; Nezer et al., 2016), while others found no effect (Pradervand et al. 2014) or mixed effects depending on dataset (Guisan et al., 2007). These studies used different species, predictors, scales, regions, and modeling algorithms, so further research is required to investigate any association between SDM grain size and AUC.

The above advantages of higher resolution environmental data in SDM may be dependent on project-specific factors, such as the quality of species records available and the goals of the research. For example, using environmental grids of a smaller grain size than the locational accuracy of the available species records is untenable. Additionally, stationary species (e.g. lichens) may be more strongly affected by local factors while highly mobile species (e.g. birds) may only be limited at broader scales. 5 Indeed, it has been shown that plant (rather than bird or mammal) species models with highest locational accuracy were those most improved by higher resolution (Guisan et al., 2007). Lastly, the utility of fine grain environmental grids may depend on habitat; flat deserts likely have less biologically relevant fine-scale spatial variation compared to mountainous forests or subtropical areas fragmented by human activity, like Hong Kong.

## 2 Study area: Hong Kong

10 Geographic data of appropriate resolution is critically important for conducting research within the Hong Kong Special Administrative Region of China, because of its complex landscape. Hong Kong exhibits dramatically variable topography, fitting numerous small islands, dozens of mountain peaks over 500 m, 733 km of coastline, and a human population of over 7 million into a land area of only 1,104 km<sup>2</sup> (Fig. 1). Seasonally variable monsoon winds deliver equatorial heat and torrential precipitation in summer, while northerly winds carry chilly dry air from continental Asia during the winter (Dudgeon and Corlett, 15 1994). However, daily temperature fluctuations are attenuated by the surrounding South China Sea and Pearl River Estuary. Hong Kong's terrain typically exhibits a stark bifurcation between some of the most densely constructed areas in the world (Lau and Zhang, 2015) and steep, vegetated slopes. Uninhabited expanses are protected as part of 24 country parks and additional special areas that cover over 40% of the territory's land (Agriculture, Fisheries and Conservation Department, 2017). Even within these more natural areas, a strong disturbance gradient encompasses grasslands, shrublands, secondary forests, 20 and old-growth *feng shui* woods that have been protected from deforestation. Historically Hong Kong has been largely stripped of its trees, and only since the end of World War II and later the establishment of the Country Park system have large swathes of forest begun to regenerate (Zhuang and Corlett, 1997). However this process is frequently reset by human-induced hill fires, which maintain predominantly upland areas as shrubland or grassland (Marafa and Chau, 1999). Hong Kong harbors several unique and restricted habitats, including mangroves in coastal areas and freshwater wetlands in the far northwest.

25 Hong Kong climate data is available within a variety of global gridded climate datasets (WorldClim 2 - Fick and Hijmans, 2017; MerraClim - Vega et al., 2017; CHELSA - Karger et al, 2017), but none of these have a resolution higher than 1 km. We suspect those global climate models underestimate variation in local climate values, even after consideration of the coarser scale. Local studies of Hong Kong meteorology have largely focused on characterizing and mitigating the effects of urbanization (e.g. Shi et al., 2018; Wang et al., 2017; Nichol et al., 2014; Liu and Zhang, 2011; Ng, 2009; Giridharan et al., 30 2004). Unfortunately, it appears the climate of Hong Kong's landscape as a whole has been given little notice, and we are unaware of long-term averaged climate rasters available for the region. Relevant studies that do exist include limited variables, and the data appear to be publicly unavailable. We are additionally unaware of Hong Kong data publicly available for vegetation indices such as NDVI, or topographic data other than elevation.

Therefore Hong Kong is in dire need of a comprehensive suite of accessible environmental GIS data, at a resolution finer than 1 km, suitable for species distribution modeling and other local applications. To this end, we developed new, 30 m resolution rasters of topography, NDVI, and 10 interpolated climate variables for each month of the year. We hypothesize that in addition to providing this finer resolution, our new climate data will indicate greater variation (measured as raster standard deviation) in climate variables than currently available global data products.

### 3 Methods

All data manipulation and geographic analyses were conducted in the R statistical computing environment (v3.3.2, R Core Team, 2016) using RStudio (v1.0.136, RStudio Team, 2015) unless otherwise noted.

#### 3.1 Topographic variables

##### 10 3.1.1 Coastline

As reclamation of land from the ocean in Hong Kong is ongoing, obtaining current data for the coastline can be challenging. Natural coastline and reservoir vectors were downloaded from OpenStreetMap (2018) and merged in QGIS to produce a shapefile representing Hong Kong land area as of January 2018. All output rasters were masked to this area.

##### 3.1.2 Elevation, slope, aspect, and roughness

15 A 5 m resolution Hong Kong digital terrain model (Lands Department, 2017) was upscaled using bilinear resampling. The resulting 30 m DEM was used as the elevation data throughout the study. Four other topographic predictor layers were derived directly from this DEM: aspect, slope, aspect\*slope, and a roughness index. These were calculated using the Hong Kong elevation raster with the terrain() function in the R raster package, using all 8 neighboring cells (queen case). Aspect was transformed from degrees to a measure of north-south exposure ("northness") by  $\cos(\text{aspect} * \pi / 180)$ .

##### 20 3.1.3 Relative elevation

A set of relative elevation layers were calculated at multiple scales, following the moving window approach of Bennie et al. (2010). They are a measure of the difference in elevation between the pixel of interest, and the lowest nearby pixel within a given radius. The radii used were 60 m, 120 m, 240 m, 480 m, and 960 m. These may be useful for a variety of purposes, but are expected to be most applicable as measures of surface water drainage and therefore soil moisture. Relative elevation has also been used in climate modeling as a proxy for cool air draining (Bennie et al., 2010; Ashcroft and Gollan, 2012), but we do not include it as a predictor here as Hong Kong lacks large valleys and other sheltered areas where this effect would be most relevant.

### 3.1.4 Distance to coast and water proximity

Water bodies adjacent to land areas can act as a temperature buffer, contribute to evaporative cooling (Lookingbill and Urban, 2003), and influence precipitation patterns (Heiblum et al., 2011; Paiva et al., 2011); therefore considering their distribution is important for climatic predictions. A distance to coastline raster was produced, using the distance() function in the raster package and a Hong Kong coastline shapefile. However, because of the complexity of Hong Kong's coastline, it appears simple distance to coast may not be the best representation of water proximity for climate predictions. Therefore, water proximity rasters at varying scales were also calculated, using a circular moving window approach similar to that described in other climate interpolation studies (Aalto et al., 2017). The radii used were 0.75 km, 1.5 km, 3 km, 6 km, and 12 km. A value of 1 means that the area within the given radius is entirely terrestrial, while 0 indicates it is entirely aquatic.

### 10 3.1.5 Urbanicity

In densely constructed areas, the urban heat island effect is expected to influence temperatures (Nichol et al., 2013; Shi et al., 2018). High rise buildings can influence temperature by blocking wind, creating shade, acting as heat sinks, and producing thermal pollution. These effects are particularly relevant for this study, as some of Hong Kong's weather observation stations are adjacent to or inside urban centers. To quantify the distribution of developed area, we used a 30 m resolution dataset of percent impervious surface (Brown de Colstoun et al., 2017), which we expect to strongly correlate with urban development. However because bulk air temperature is not expected to vary at a granular (30 m) scale, this data was smoothed using a Gaussian moving window at three scales (sigma = 10, 50, 100) to create 'urbanicity' layers.

## 3.2 Climate variables

Climate interpolators are often faced with the challenge of estimating climate parameters over a large area with sparse weather station observations, at least in part of the region considered (e.g. Hu et al., 2016). In contrast, interpolation in Hong Kong is benefitted by a relatively small geographic area and a quite dense network of weather data provided by dozens of permanent weather stations. Here we use thin plate spline interpolation, which fits a curved surface to irregularly distributed points.

Weather station observation data and geographic coordinates were downloaded from the web portal of the Hong Kong Observatory (2018). As the goal was to produce a representation of long-term but modern climate, measurements over 20 years (1998 to 2017) were included. To ensure averages were reliable, weather stations were only included for interpolation of each variable if at least 8 years of complete data were available within the 20 year window. The minimum number of stations used for each model is provided in Table 2. Monthly observations of ten variables were obtained: maximum temperature, mean daily maximum temperature, mean daily temperature, mean daily minimum temperature, minimum temperature, mean dew point, mean relative humidity, mean wind speed, mean air pressure, and total rainfall.

30 Spatial climate modeling consisted of two main steps. First, a generalized linear model was built for each climate variable for each month of the year. Six topographic climate predictors were used as model building candidates: elevation, log-transformed distance to coast, exponentially transformed fine and coarse water proximity, log-transformed urbanicity (sigma = 50), and

‘northness’ - the cross product of aspect and slope. The water proximity layers were products of combining multiple scales into fewer predictors: fine was the sum of 0.75 km, 1.5 km, 3 km scale rasters, while coarse was the sum of 6 km, and 12 km. All model predictors were tested for collinearity and no problems were found. All predictors were initially included, then pared down in each regression model using stepwise bidirectional selection based on AIC, using 4 degrees of freedom as a penalty to make predictor selection stricter than the default. The resulting model was used to calculate a climate value at each grid cell based on a linear relationship with the selected predictors.

Second, to adjust for local variation in climate that is not associated with topography, the linear model residuals at each station were calculated and interpolated using the thin plate spline approach implemented in the fields R package. The lambda smoothing parameter, which determines how closely the fitted surface matches input values, was set to 0.01. A fairly low lambda value was selected because of the relatively high confidence in the long-term averaged weather station values. This effectively produces a smoothed layer of local deviation from the linear model, which was used to additively adjust the results of the linear models and produce finalized climate rasters.

We measured the spatial predictive ability of models using ten-fold cross validation (Dobesch et al., 2007). In each validation round, 10% of weather stations were reserved as a test dataset and the remainder were used for training. Average root mean squared error of the test data subset from the final model prediction was used as an error measurement. To normalize these error measures across the climate variables, we adjusted them as a percentage of the standard deviation of the initial weather station values measured.

The monthly models were then summarized into raster layers that characterize yearly climatic means and variation. These include 19 "bioclimatic" variables using the biovars() function in the dismo R package (Hijmans et al., 2017), which are specifically suited for species distribution modeling and other ecological purposes. This also allows our data to be compared with other climate data products that use the same calculations. Because those calculations only use rainfall and average daily maximum and minimum temperatures in each month, we also produced yearly average layers of dewpoint, relative humidity, mean daily temperature, air pressure, and wind speed. Also provided are layers of highest and lowest average monthly extreme temperatures, and their difference (extreme temperature annual range). These two variables characterize temperature extremes experienced in a given location better than the bioclimatic variables.

For comparison with global climate data products, we resampled bioclimatic variables to the same (1 km) resolution as WorldClim using bilinear interpolation. Only pixels present in both data products were used for comparisons.

### 3.3 Remote sensing data

Normalized difference vegetation index (NDVI) is a common metric of vegetation presence and density derived from satellite imagery. To calculate normalized difference vegetation index (NDVI), Landsat images (U.S. Geological Survey, 2018) of Hong Kong were obtained. We downloaded one image from March 2016 that covers much of Hong Kong except for the far eastern

areas, and is free of clouds. This was supplemented with an image from March 2018 after adjustment, so that all land areas of the region were included. NDVI calculations were completed using the standard equation:

$$NDVI = (NIR - Red) / (NIR + Red) \quad (1)$$

Where NIR is near-infrared (Landsat band 5: 0.851 to 0.879  $\mu\text{m}$ ) and Red is visible red radiation (Landsat band 4: 0.636 to 0.673  $\mu\text{m}$ ). The resulting NDVI value varies between 1 and -1, where higher values correspond with denser vegetation.

## 4 Results and discussion

Results of this environmental analysis of Hong Kong include 48 rasters and one vector file. All rasters are provided at an identical 1 arc second (0.03 km) resolution and in the WGS84 geographic coordinate system. Summary values and filenames are provided in the data repository.

### 4.1 Topographic variables

Distance to coast results show that approximately 42% of Hong Kong's land area is within 1 km of the coastline. However it is apparent that inland areas often feature steep inclines, as half of Hong Kong's land is above 84 m elevation.

For variables like relative elevation, urbanicity, and water proximity, the ideal scale of raster calculation is dependent on the desired effect to be captured, and perhaps other characteristics of the landscape in question. For this reason, we provide the rasters at multiple scales.

Urbanicity results show that the majority of land in Hong Kong is not near urban areas, as the median raster value is below 4% urban at all scales calculated. It is also apparent that inferring urban development from impervious surface is not ideal, as sometimes bare soil or rock are sensed as impervious. Also, there is little ability for such a measure to differentiate between a dense urban core of high-rises, and large paved areas (such as parking lots or airports). Unfortunately, accessible data on the geographic distribution of the urban environment in Hong Kong is limited. For climate modeling, an urbanicity measure that takes into account building height or population density at a 30 m or finer scale could be preferable.

### 4.2 Climate variables

Minimally, 32,024 monthly weather station measurements over 20 years were used to construct climate models for all months and variables at finer resolution compared to global datasets (Fig. 2). High weather station density and availability of data on multiple candidate topographic climate-forcing factors allowed for high confidence in many climate variable models, especially those related to temperature (Figs. 3, 4). The climate interpolation results include monthly models of ten variables including temperature, precipitation, and humidity, making a total of 120 individual models produced (monthly models of three temperature variables are shown in Fig. 5). For all variables, the predictors included in monthly models are displayed in Figure 6, and the number of stations with data included is in Table 2.

#### 4.2.1 Temperature

Temperature was found to vary considerably across Hong Kong, with more than 6°C difference in mean annual temperature between the highest mountain peaks (>900 m, <18°C) and some low-lying urbanized areas (>24°C). While mean and minimum temperature are highest in urban areas, maximum temperature shows a different pattern with a maximum in inland valleys in the northern New Territories. The high accuracy of temperature models is likely due to a strong association with elevation; elevation was by far the most commonly included predictor for temperature models (Fig. 6). Urbanicity was important for mean and minimum temperature, but not maximum temperature. Water proximity and coast distance were differentially included depending on the variable, while aspect\*slope rarely had an effect. A few special notes on the limitations of predicted temperature values in dense urban areas: temperature predictions of our landscape-level climate models will not reflect the high spatial variation in temperature found in urban microclimates. Although the manned Kowloon HKO weather station is inside a densely populated area, as pointed out by Nichol and To (2012) it is still in a small parklike area surrounded by trees, and therefore is not representative of the most densely urbanized areas of Hong Kong. Other stations in urban areas are similarly near green spaces or otherwise open areas. Higher resolution (say 5 m or 1 m) studies of urban thermal distributions would strongly benefit from analysis of wind patterns, building height, thermal pollution, and other factors (e.g. Shi et al., 2018). Therefore granular, ground-level temperatures in urban areas are likely substantially different than the broader air temperature values our models provide. One area of particular interest is the Hong Kong Airport, a massive area reclaimed from the ocean, north of Lantau Island. The weather station here has the highest urbanicity value, because the airport is mostly impervious surface. However it lacks properties of truly urbanized areas, with no permanent population lacking typical urban morphology. Therefore climate variables in this area may be biased, especially for variables like wind speed that would be affected by the presence of tall buildings. The airport weather station often had the highest mean temperatures recorded, perhaps indicating that extensive impervious surface is more important than wind blockage or thermal pollution for maintaining high temperatures.

#### 4.2.2 Rainfall

In our models, the highest annual rainfall (bio12) areas in Hong Kong (>2500 mm annually) are inland and at high elevations, presumably because of condensation from humid air as it passes over mountains. Areas near the coast, particularly small outlying islands and the eastern coast in Lung Kwu Tan receive the lowest amount of annual rainfall (<1600 mm). Precipitation of driest month (bio14) was uniformly low, ranging from 20 to 40 mm, but the relative pattern of high and low precipitation areas remained similar. The most commonly included model predictor was fine-scale water proximity. Elevation was predictive for 5 out of 12 months, but few other topographic predictors were useful. Seasonality of rainfall in Hong Kong is strong. Averaged across all locations, 52% of total yearly rainfall was recorded in three months (June through August). Although rainfall models were informed by more weather stations than any other climate variable (Table 2), they have the highest relative standard error (Fig. 3) and therefore the lowest accuracy. Because they are influenced by both global and locally variable wind patterns, precipitation distributions are notoriously difficult to predict, especially in urban areas (Cristiano et al., 2017). Our relatively poor results may be explained by this, as well as lack of appropriate local predictors. We did not explore

the possibility of using global circulation models as predictors because we expected that they would affect areas of Hong Kong equally, but perhaps they would be beneficial.

#### 4.2.3 Dew point, humidity, pressure, and wind speed

Dew point exhibits a similar pattern to other temperature variables, with mean annual dew point ranging from 15.5°C at mountain peaks to around 19°C on small islands and lower areas. Mean annual relative humidity reaches a maximum of about 90% at Tai Mo Shan, while many urban areas in Kowloon, Tuen Mun, and Yuen Long are between 70 and 75%. Surprisingly, mean annual air pressure has a positive correlation with elevation; the highest values (reaching 1014 hPa) are at mountain peaks, and particularly low values (as low as 1012.5 hPa) in coastal areas of southern and western Hong Kong. Mean annual wind speed is also strongly associated with elevation, with mean annual values above 30 km/h on Lantau Island mountain peaks, down to below 5 km/h in interior low elevation areas of the New Territories.

#### 4.2.4 Climate variables general discussion

Similar to other climate interpolation studies, bias in the physical locations of automatic weather stations may be of concern. Weather stations are often intentionally placed in flat, open areas with the goal of measuring weather that is relevant to a broad geographic area, rather than locations that may experience unique local climate. It may be for this reason that Slope\*Aspect was infrequently useful for model construction, as few stations are on steep slopes. Elevational distribution of stations may also be a source of bias. Although a weather station operates at the highest point in Hong Kong (Tai Mo Shan, 955 m), there are only two other stations above 600 m.

We used cross-validation to measure the spatial predictive ability of the climate models. However, this method is only able to test models against locations where weather stations are present, and validation based on an independently collected dataset would be ideal. One common validation method is to use weather data loggers placed across elevational and land-use gradients (Meineri and Hylander, 2017). Such an approach would allow for explicit testing and comparing predictiveness of climate products for different areas of Hong Kong.

Our new climate models are compared with a recent global climate dataset to identify differences in predictions of Hong Kong climate values (Fig. 7). Worldclim 2 was produced using a similar interpolation approach with regression modeling and thin plate spline interpolation, but also included satellite-derived covariates in addition to topography (Fick and Hijmans, 2017). Because Worldclim incorporates vast amounts of data from multiple databases covering overlapping geographic and political entities, it is difficult to ascertain exactly which individual weather stations were included, and we were unable to determine whether any Hong Kong weather stations were included or if the datasets are completely independent. However, the model predictions differ substantially (Figs. 1, 7; Table 3). The new models generally indicate greater spatial variation than Worldclim, with cool areas colder, warm areas hotter, and wet areas wetter. For example in average low temperature of coldest month (bio6), high elevation areas could be more than 2°C lower, and urban areas more than 2°C higher than Worldclim indicates (Fig. 7a). To further quantify differences in values between these two datasets, for each of the 19 bioclimatic variables we calculated the standard deviation of raster values (Table 3). All of our interpolated climate rasters had a higher standard

deviation than their Worldclim 2 counterparts. These results suggest that unless global climate models increase in resolution and accuracy, regional models will remain critical for local applications.

### 4.3 Remote sensing variable

The NDVI data represents vegetation quality and density based on two merged satellite images, both in March of their respective years. Although this is only an instantaneous representation of NDVI, we expect it to correlate strongly with relative vegetation density as well as unvegetated areas throughout the year. NDVI values above 0.4 include Hong Kong's densest forests, while unvegetated or urbanized areas are well below 0.1. The densest vegetation ( $> 0.4$  NDVI) in Hong Kong tends to be on slopes between 100 m and 400 m elevation (Fig. 8), and is distributed between Hong Kong Island, Lantau Island, and the New Territories. One exception is the verdant mangrove forests, at sea level. The patchy distribution of high density vegetation likely reflects the effects of historical deforestation. The largest patches are found on the southeastern slopes of Tai To Yan in the New Territories. The relative distribution of NDVI classes along Hong Kong's elevational gradient is shown in Figure 8. Vegetation index values vary depending on time of year and with recent weather conditions, so much more future work could be done to characterize how this measure changes over time. The limiting factor is the availability of data of adequate temporal resolution, as many satellite images of Hong Kong are obscured by cloud cover or degraded by poor air quality.

### 4.4 Next steps

Important gaps in Hong Kong geographic data remain. Finer grain, microclimatic variables (Lembrechts et al., 2018) based on remote sensing data and temperature loggers could be a next step for local climate modeling. Models projecting future climate scenarios would enable biodiversity change predictions, and additional variables like cloud cover and solar radiation would be useful. A discrete classification of habitat type would be useful for ecological research. A series of studies in the past, commissioned by the Hong Kong government, classified Hong Kong's terrestrial habitats (e.g. Environmental Resources Management, 2009), however the results of these very thorough remote sensing studies are not accessible. Quality soil type data is lacking, and as mentioned before a better index of population density or built-up area would be welcomed. Availability of such data would complement the results of this project, and benefit geographic studies in Hong Kong.

## 5 Conclusions

This diverse set of 30 m resolution topography, climate, and remote sensing data include the first published interpolation of long-term climate averages specific to Hong Kong. Our findings suggest that global climate datasets are limited by their resolution, and underestimate local climate variability. Therefore the availability of such local data will remain critically important for the foreseeable future. This new data will allow for a new generation of studies in Hong Kong, and enable connections between environmental data and biotic patterns at a much finer scale than previously possible. Aside from clear uses in conservation, ecological and biogeographic research, we also expect this freely accessible dataset to be broadly applicable for many sectors, including tourism, hydrology, recreation, agriculture, mapmaking, and real estate.

## 6 Data availability

GeoTIFF raster and shapefile documents can be downloaded from figshare: <https://figshare.com/s/3a5634e36e80dc33444c> (or <https://doi.org/10.6084/m9.figshare.6791276> (once data is published)). The readme document in the repository includes file names, descriptions, and summary statistics for all provided rasters. Individual monthly rasters for each of the 10 climate variables are available from the authors upon request.

*Author contributions.* BAM acquired initial data, conducted modeling, and prepared the dataset. BAM and BG prepared the manuscript.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* We thank Ocean Park Conservation Foundation for supporting this research. This project would not have been possible without the Hong Kong Observatory, which works tirelessly to maintain their weather station network and ensure the resulting data is accessible. We also thank Eric Meineri for comments and advice while planning our analyses.

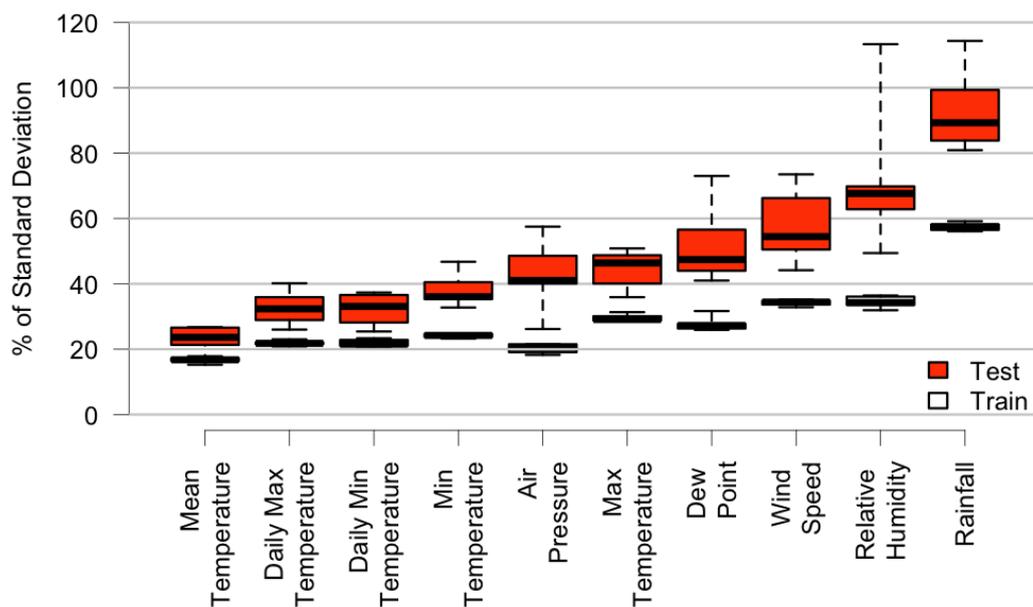

**Figure 1.** Hong Kong geography. The three highest peaks in the territory, as well as the highest point on Hong Kong Island are marked. Areas protected as Country Parks are highlighted in green.

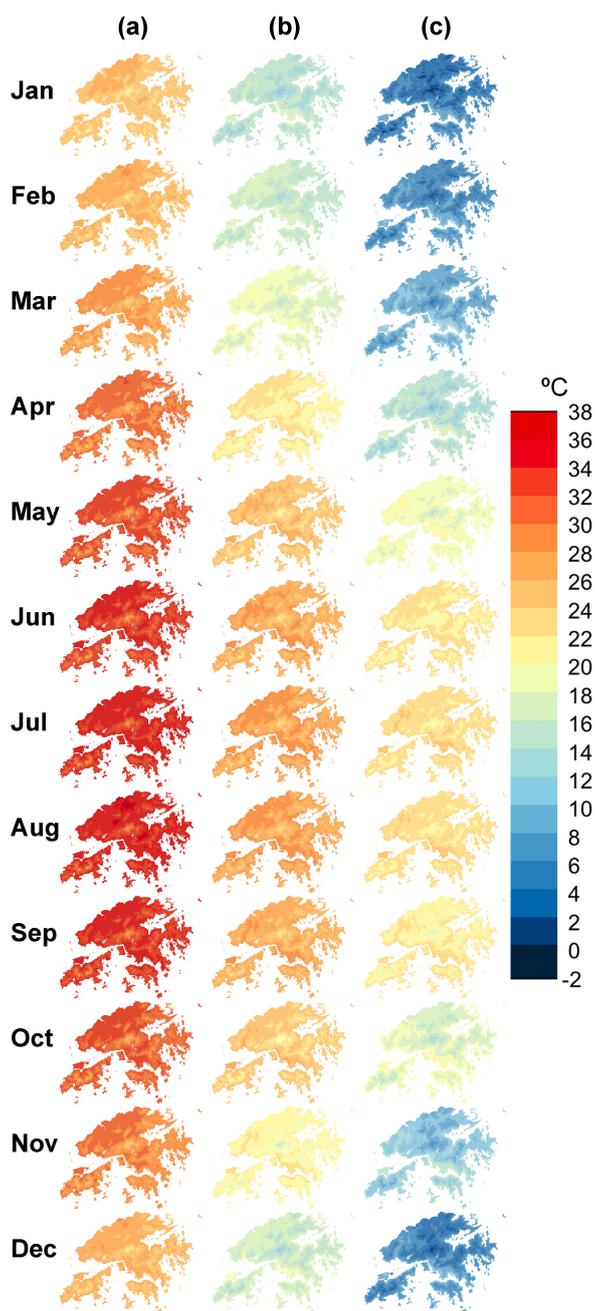

**Figure 2.** Comparison of average high of warmest month (bio5) model results for Hong Kong. (a) is from our newly interpolated climate models at 30 m resolution, while (b) is 1 km resolution data available as part of Worldclim 2 (Fick and Hijmans, 2017). Not only is the resolution markedly improved, but also the temperature values are more varied, for instance on the large southern islands.

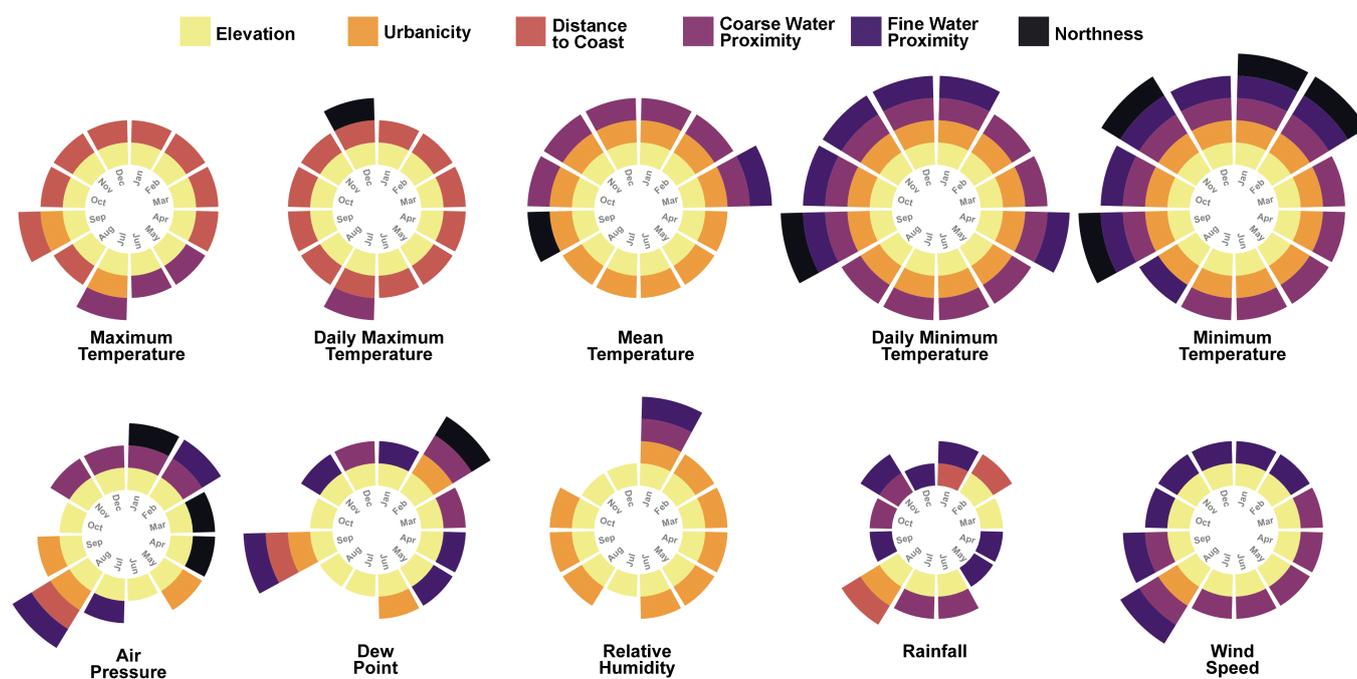

**Figure 3.** Adjusted  $r^2$  values of initial (pre-spline) regression models. Each boxplot includes 12 points, one for each monthly model. Temperature variation, especially mean temperature, was best explained by linear modeling, while rainfall was predicted the most poorly.

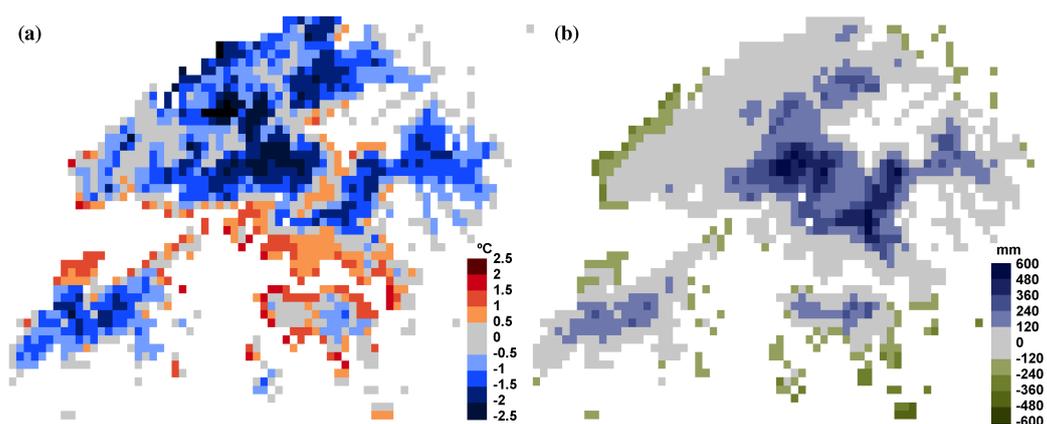

**Figure 4.** Relative magnitude of training and testing dataset errors, from 10 validation rounds of climate variable modeling. A value of 100 indicates for that climate model, that the average difference between the value recorded at a given weather station and the value predicted by the model at that location, is equal to the standard deviation of the initial set of all values recorded at all weather stations for that climate variable.

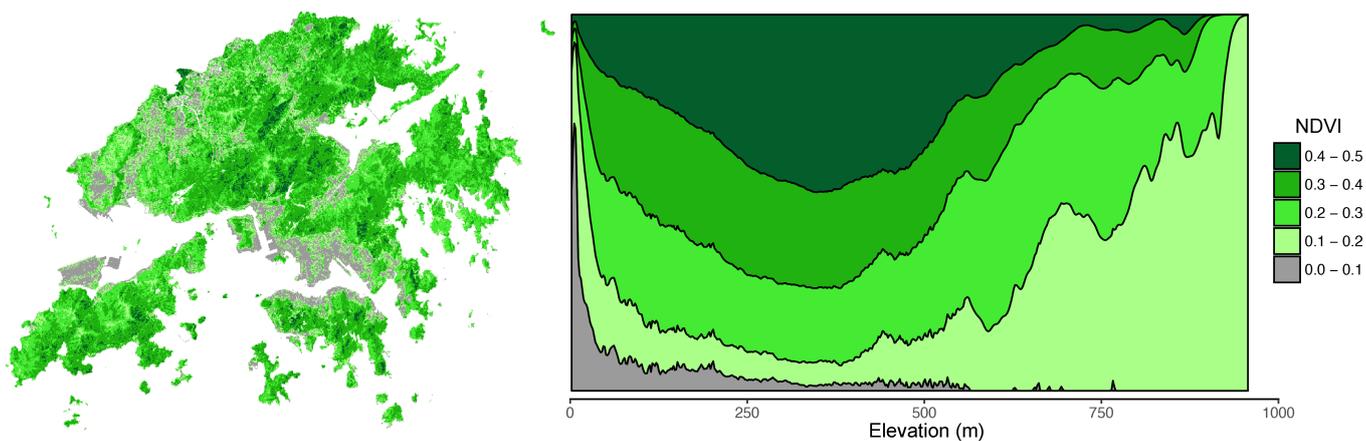

**Figure 5.** Model results for three of ten interpolated climate variables. (a) Maximum temperature, (b) Mean temperature, and (c) Minimum temperature.

**Figure 6.** Regression predictors included in monthly models for 10 climate variables. Each predictor is represented by a different color. Minimum and mean temperature variables were most predictable, consistently including elevation and urbanicity. Rainfall patterns were most difficult, with the fewest predictors included.

**Figure 7.** Differences between results of this study and Worldclim 2 (Fick and Hijmans, 2017) values. (a) is average low temperature of coldest month (bio6), with red where the local model is warmer than WorldClim, and blue is colder. (b) shows annual precipitation (bio2), with blue where the local model predicts more rainfall than WorldClim, and tan is less rainfall. Our model results were resampled to 1 km resolution using bilinear interpolation to allow for these comparisons.

**Figure 8.** NDVI class composition over Hong Kong's elevational range. The majority of land area near sea level is below NDVI 0.1, while Hong Kong's highest elevation areas are between 0.1 and 0.2, indicating short vegetation. The elevation range with proportionally the most dense vegetation (0.4 to 0.5 NDVI) is 300 to 400 m.

**Table 1.** Raster product descriptions, units, and 5th, 50th, and 95th percentile values.
